--	----

INTRODUCTION

Ground water, a plentiful and largely underdeveloped resource of Wisconsin, has good to excellent chemical quality in most places. This resource is readily available in most parts of the State for municipal, industrial, and rural uses. In 1970, about 0.5 billion gallons of ground water a day was pumped in Wisconsin for all uses (Murray and Reeves, 1972). In addition, underground reservoirs discharge an average of 16 billion gallons per day of water of relatively constant temperature and uniform quality, which maintains the base flow of streams and the level of lakes (Holt, 1964).

The quality of ground water greatly affects its use by municipalities, in industry, and on the farm. In addition, the quality of ground water discharged to streams and lakes governs the quality of the base flow of streams and water in the lakes. More than 1.5 million people (Murray and Reeves, 1972) living in 445 Wisconsin communities (Wisconsin Department of Natural Resources, 1970) use ground water and are, naturally, concerned about its quality. Industrial users need to know about harmful or beneficial chemicals in processing water and the temperature of ground water used for cooling. Agricultural use is least demanding on water quality, but knowledge of dissolved minerals that may affect crops, animals, or soils is necessary. Fish are sensitive to water temperature and quality, and most trout live in reaches of streams that receive large discharges of ground water (Threinen and Poff, 1963).

Ground-water research, including collection of basic data on quantity and quality, by the Wisconsin Geological and Natural History Survey (WG&NHS) in cooperation with the U.S. Geological Survey, has continued for nearly three decades. This includes a long history of close cooperation with the Wisconsin Department of Natural Resources (DNR), which has the responsibility for regulating the use and protecting the quality of ground water. The primary concerns of the cooperative studies have been the prediction of how much, where, and when ground water will be available; the determination of water quality; the effects of development and use of the resource; and the impacts of surface and subsurface contaminants on local and regional ground-water systems and on streams and lakes.

Purpose and Scope of Report

One purpose of this report is to summarize and interpret available information on the quality of ground water in Wisconsin. Major sources for this information are the more than 30 technical reports that describe ground-water resources and quality in river basins, counties, and special study areas.

Another purpose is to present a background of chemical-quality data on ground water as it occurs in natural and man-modified environments. These data constitute a base for planning and managing the water and land resources of Wisconsin.

A third purpose is to describe the current monitoring program for ground-water quality and to assess the need for its acceleration.

Because ground water in Wisconsin is generally free of contaminants, table 1 indicates the generally natural, or baseline, quality of water. The term "natural" quality used in this report may include minor quality changes resulting from long-term changes in land and water use. The "natural" quality data are essential for monitoring changes in water quality. Contamination of ground water constitutes a departure from "natural" quality.

The 3,388 chemical analyses given in table 1 were acquired as part of numerous cooperative investigations (fig. 1). Many are comprehensive--including determination of all major cations and anions and chemical-physical characteristics. Other analyses include only a few components. The analyses are not equally distributed geographically, however, because priority for collection was determined by areas of major water use and areas of current and anticipated water problems. Little or no information is available for some places.

Table 1 includes only analyses in computer storage as of April 1973, and figure 1 includes only those sites represented in table 1. Several hundred analyses remain to be put into storage. The counties having significant quantities of analyses remaining to be stored are Clark (50), Green Lake (10), Juneau (5), Langlade (10), Marathon (20), Marquette (5), Menominee (5), Portage (70), Shawano (5), Waupaca (65), Waushara (3), and Winnebago (45). Other counties have lesser quantities. All remaining analyses plus other analyses obtained after April 1973 will continue to be placed into storage.

Included with the inventory (1,159 single-analyses sites) of "natural" quality are repetitive samples collected at 731 monitoring sites (fig. 1 and table 1). The purpose of this monitoring is to determine changes in ground-water quality, both regional and within an aquifer. The monitoring includes studies of the movement of the deeply buried highly mineralized water in eastern Wisconsin in relation to areas of major pumpage. Water samples for monitoring purposes are collected generally at 1-year intervals because regional changes in ground-water quality are slow.

Data on water-quality constituents, such as heavy metals, radio-chemical parameters, temperature, strontium, nitrite, and hydrogen sulfide, as well as data on well construction and geology, have been omitted from table 1. However, these data are in computer storage and are available on request to the District Chief, U.S. Geological Survey, Madison, Wisconsin.

Acknowledgments

Acknowledgment is made to the Wisconsin State Laboratory of Hygiene, the Wisconsin Department of Natural Resources, and to other State and local agencies for making water-quality analyses available. Appreciation is expressed to citizens, industries, and local and State agencies for permitting the collection of water samples.

Special recognition is given the many staff members, who expended considerable effort in a brief period of time to prepare data for computer processing and for this report.

THE "NATURAL" QUALITY OF GROUND WATER

Dissolved Minerals in Ground Water

Ground water dissolves, transports, and deposits minerals. The climate, including the amount and chemical character of precipitation, governs the amount of water available for solution, subsequent dilution, and the movement of dissolved material. The characteristics of rocks and soils govern the rate of water movement and the amount of mineral solution. The growth and decay of organic substances contribute to the decomposition of mineral matter and accelerate the rate of solution.

All rocks are soluble in water to varying degrees. Limestone (dolomite) beds in parts of southwestern and eastern Wisconsin have been dissolved along joints and bedding planes, leaving passageways for the flow of water. Springs and seeps mark the exits of many of these passageways. Less soluble rocks, such as the crystalline rocks of northern Wisconsin and the quartz sand of the outwash plains, decompose slowly but still contribute some dissolved minerals to ground water.

The mineral content of ground water changes as it travels from the land surface downward through soil and varied layers of rocks, then laterally, until it discharges from springs, seeps to rivers and lakes, or is pumped to the surface by wells. Generally, the concentration of minerals in ground water increases with the length of time the water is in contact with rocks and soil. Because ground water may dissolve different minerals from place to place, the composition and chemical type of the water may change significantly between sampling points.

Ground water also absorbs wastes readily, such as effluent from septic tanks, industrial and farm wastes, municipal sewage, and leachate from solid wastes. Many other materials, such as road salt, fertilizer, and petroleum products, may enter a ground-water system.

Amount of Dissolved Solids in Ground Water

The amount of mineral matter dissolved from rocks, transported underground, and discharged by springs, seeps, and wells is large. However, because ground water is generally free of visible sediment, the volume of minerals removed by solution is not apparent. In Wisconsin, the average dissolved-solids content of ground water discharged to lakes and streams and from wells is generally about 200 mg/l (milligrams per liter). Ground-water discharge in the State is estimated to be 16 billion gallons per day--or about 285,000 gallons per day per square mile (Holt, 1964). Computed on an annual basis, 87 tons per square mile of mineral matter is being dissolved from soil and rocks. The dissolved mineral yield of ground water for the entire State, about 5 million tons per year, would require 100,000 coal cars to haul. About 150,000 tons per year of the total mineral yield was pumped in 1970, along with about 180 billion gallons of water from wells (Murray and Reeves, 1972).

The magnitude of the dissolved mineral content of ground water is striking, when compared with the volume of sediment derived from surficial erosion and transported in Wisconsin's streams. The average annual discharge of suspended sediment in streams is about 100 tons per square mile (Holt, 1973), whereas 87 tons per square mile of mineral matter is dissolved annually from soil and rocks, as stated previously.

Not all the minerals dissolved by ground water are transported from the State; a part precipitates as solids, such as marl, in lakes and swamps, and some becomes sorbed by the suspended and bedload sediment in streams (Wcidman and Schultz, 1915).

The Chemical Quality of Ground Water

The "natural" chemical quality of ground water differs considerably between aquifers, within aquifers, and from one drainage basin to another. This difference is related primarily to the chemical composition of the soil and rocks and the length of time the water has been in contact with them.

The quality of water discharged from glacial drift and bedrock (fig. 2) is related generally to the chemical and physical character of these sediments and rocks (fig. 3 and 4). Areas in northern and central Wisconsin having less than 100 mg/l dissolved solids in ground water relate to extensive deposits of sand and gravel underlain by crystalline rock, where ground water moves rapidly and for relatively short distances between areas of recharge and discharge (Oakes and Cotter, 1973; Young and Hindall, 1972; Devaul and Green, 1971). Areas having between 100 and 250 mg/l dissolved solids in ground water are characterized by glacial deposits, such as moraines and outwash, which contain fragments of dolomitic limestone and are underlain by shallow bedrock of dolomitic sandstone and dolomitic limestone (Olcott, 1968; Young and Hindall, 1971; Young and Hindall, 1972; Oakes and Hamilton, 1971). Areas having more than 250 mg/l dissolved solids are characterized by thick deposits of glacial drift that includes fragments of dolomitic limestone, lake clay, and shallow dolomitic limestone (Young and Skinner, 1973; Skinner and Borman, 1970; Olcott, 1968; Cotter, Skinner, and Wentz, 1969).

The quality of water discharged from deep bedrock aquifers (fig. 5) is related to the chemical and physical character of the aquifers (fig. 4) and to the generally great length of time the water has been in contact with the rocks. The central and western areas of the State, having less than 250 mg/l dissolved solids in ground water, relate to sandstone aquifers in which the water generally moves only a few miles between recharge and discharge points (Hindall and Borman, 1972; Young and Borman, 1971; Devaul and Green, 1971). In the southern, eastern, and parts of the western areas, where dissolved solids range from 250 to 500 mg/l, ground water is generally deep and moves several miles between recharge and discharge points (Hindall and Skinner, 1971; Cotter, Skinner, and Wentz, 1969). The water in these aquifers is partly confined by layers of shale and dolomitic limestone.

Near the margins of the State, where dissolved solids are more than 500 mg/l (Skinner and Borman, 1970), ground water moves with extreme slowness in deeply buried sandstone and shale beds and may be locally restricted by

structural or lithologic barriers (Ryling, 1961 and Olcott, 1966) (fig. 5). Such water contains large amounts of sulfate, chloride, calcium, and magnesium. Highly mineralized and localized water in fractures and joints in Precambrian sandstone, basalt, and crystalline rock in northern Wisconsin is not shown on the map.

The source and significance of chemical constituents and properties commonly found in ground water are given in table 2.

Chemical analyses, given in table 1, indicate that nuisance amounts of iron, manganese, nitrate, and similar constituents occur locally in the "natural" ground waters of Wisconsin. Water high in iron content is derived generally from the glacial drift or from sandstone (Holt, 1964). In sandstone, iron content generally increases with restriction of ground-water movement (Olcott, 1966). In glacial drift, iron content is generally high in areas of poor drainage, such as wetlands (Holt, 1965 and Cline, 1965).

Fluoride content is significant in deep aquifers in eastern Wisconsin (fig. 6) (Holt, 1964), but fluoride content of ground water is low in the remainder of the State.

Hardness of ground water differs over most of the State. The softest water is in the north-central part, whereas the hardest is in the eastern, southern, and southwestern parts (Holt, 1964).

The temperature of ground water is generally uniform throughout the year, especially where 60 feet or more below the land surface (Summers, 1965). It approximates the average annual air temperature.

Interpretation of the chemical character of ground water in each of the principal river basins of the State is available from a series of 12 river-basin reports and from 15 county reports listed in the bibliography.

CONTAMINATION OF GROUND WATER

In Wisconsin, ground water is believed by many to be free from the threat of pollution. This belief is generally correct because many ground-water reservoirs are protected from surface pollutants by clayey soil and by thick layers of clay and shale. However, in areas where ground water is not thus protected, the possibility of contamination exists. Other means of protecting ground-water supplies will be forced upon users if increasing amounts and types of waste are disposed of in areas of ground-water recharge.

Most contamination of ground water in Wisconsin is local. Although ground-water contamination is reported from nearly every county, no evidence has been found that a major part of an aquifer is contaminated. Most contaminants introduced into ground water travel only a short distance before they are attenuated through dilution, absorption, and filtration or are discharged to streams and lakes.

Table 2.--SOURCE AND SIGNIFICANCE OF CHEMICAL CONSTITUENTS AND PROPERTIES LISTED IN TABLE 1.

Constituent or property	Principal source or cause	Significance
Iron (Fe) and Manganese (Mn)	Dissolved from the common iron- and manganese-bearing minerals. Iron is present in most rocks, whereas manganese is not as common. Both iron and manganese are often found in large quantities in acid waters.	Iron oxidizes to a reddish-brown sediment. Manganese oxidizes to a brown-black sediment. Stain utensils, enamelware, clothing, etc. Make water unsatisfactory for food processing, dyeing, laundering, bleaching, beverages, textiles, and processing of ice. USPHS (1962) drinking-water standards suggest that iron not exceed 0.3 mg/l, and manganese not exceed 0.05 mg/l.
Calcium (Ca) and Magnesium (Mg)	Dissolved principally from gypsum, limestone, and dolomite, but present in nearly all rocks. Large quantities are found in brines.	Impart hardness and scale-forming properties to water, soap consuming. (See hardness.) Make water unsuitable for laundries, steam plants, textile processing, and dyeing. USPHS (1962) drinking-water standards do not contain suggested limits for calcium or magnesium.
Sodium (Na) and Potassium (K)	Dissolved from practically all rocks and soils. Found also in sea water, brines, and sewage.	Cause boiler foaming when present in large amounts. Combine with chloride to give a salty taste. Large quantities limit use for irrigation.
Bicarbonate (HCO_3^-) and Carbonate (CO_3^{2-})	Formed by action of carbon dioxide in water on carbonate rocks, such as limestone and dolomite.	Raise the alkalinity and usually pH of water. In combination with calcium and magnesium, cause carbonate scale and carbonate hardness. Heating releases corrosive carbon dioxide. Not considered to be significant to general health.
Sulfate (SO_4^{2-})	Dissolved from shale and gypsum or formed by oxidation of sulfides. Commonly associated with coal mining. Contributed by some industrial wastes.	With calcium, forms hard scale in steam boilers. Imparts cloudiness to ice. Causes bitter taste when combined in large amounts with other ions. Calcium sulfate is considered to be beneficial in brewing processes. USPHS (1962) drinking-water standards recommend that sulfate content not exceed 250 mg/l.
Chloride (Cl)	Dissolved in varying amounts from all soils and rocks. Also found in brines, sea water, and sewage.	Calcium and magnesium chloride may increase the corrosive activity of water. In large amounts gives salty taste. USPHS (1962) drinking-water standards recommend that chloride content not exceed 250 mg/l.
Fluoride (F)	Small amount dissolved from most rocks and soils. Fluoride concentrations over 1 mg/l usually found in association with sodium waters. Primary source of high concentrations is industrial waste. Added to many municipal supplies by fluoridation.	May cause mottling of enamel on teeth of children if present in amounts in excess of 1.5 mg/l. About 1 mg/l reduces incidence of tooth decay in children (Maier, 1950). USPHS recommends control limits based upon annual average of maximum daily air temperatures. (See USPHS Advisory Committee Report, 1962: Publication No. 956, p. 8.) The optimum for Wisconsin is about 0.7 mg/l, and about 1.4 mg/l is considered the upper limit.
Nitrate (NO_3^-)	Contributed principally by decaying organic matter, nitrate fertilizers, and sewage. Small amounts available from most rocks and soils.	Investigations by Comly (1945) indicate that high concentrations (more than 44 mg/l expressed as NO_3^-) may cause methemoglobinemia (infant cyanosis). USPHS (1962) drinking-water standards suggest a limit of 45 mg/l. Encourages growth of algae and other organisms that produce undesirable tastes and odors. Higher than local average may indicate pollution.
Dissolved solids	Dissolved mineral constituents, the principal ones of which are listed above in this table.	USPHS (1962) drinking-water standards recommend that dissolved solids should not exceed 500 mg/l; however, 1,000 mg/l is considered to be usable under certain circumstances. Water containing more than 1,000 mg/l dissolved solids is unsuitable for many purposes.
Hardness as CaCO_3	In most water nearly all the hardness is due to calcium and magnesium. Iron and manganese also cause hardness.	Hard water consumes soap before a lather will form, deposits soap curd on bathtubs, and forms scale in boilers, water heaters, and pipes. Water of hardness less than 60 mg/l is considered soft; 61 to 120 mg/l, moderately hard; 121 to 180 mg/l, hard; more than 180 mg/l, very hard (Swenson and Baldwin, 1965, p. 17).
pH (hydrogen ion concentration or activity)	A measure of the acidity or basicity of water. Acids, acid-generating salts, and free carbon dioxide lower the pH. Carbonates, bicarbonates, hydroxides, phosphates, silicates, and borates generally raise the pH.	A pH of 7.0 indicates neutrality of a solution. As values increase higher than 7.0, alkalinity increases; as values decrease below 7.0, acidity increases. Corrosiveness of water generally increases with decreasing pH. However, excessively alkaline water also may attack metals. Water pH that tends to remain near neutral when counteracted by an acid or base is considered to be buffered.
Temperature	Results from climatic conditions, use of water as a cooling agent, or industrial activities.	Affects usefulness of water for many purposes. For most uses, water of uniformly low temperature is desired. Shallow well-water temperature fluctuates seasonally. Ground water from moderate depths is nearly constant in temperature, which is near the mean annual air temperature of the area. In very deep wells, water temperature generally increases about 1° F with each 60 feet increment of depth. Seasonal fluctuations in temperature of surface water are comparatively large, depending on the volume of water.

Contamination of ground water occurs generally within shallow aquifers of sand and gravel or in dolomitic limestone unprotected by overlying clayey soils or by shale. Areas having the greatest potential for shallow ground-water contamination are as follows:

1. Outwash and river alluvium overlain by permeable soils--such as the sand plain of central Wisconsin, the outwash near the Kettle Moraine of southeastern Wisconsin, the outwash sands of Barron County, and the valleys of the lower Rock and Wisconsin Rivers.
2. Limestone (dolomite) at or near the surface or overlain by permeable sand and gravel, such as in southwestern Wisconsin and in Door County.
3. Crystalline rock overlain by thin soils and sand, such as in north-central Wisconsin.

In a small area of southeastern Wisconsin, "natural" highly mineralized water may be encroaching locally into fresh-water zones (Ryding, 1961 and Olcott, 1966). In the northern part of Milwaukee County, fresh water near deeply buried saline water is being monitored to detect possible changes in quality and movement toward centers of pumping. In central and eastern Sheboygan County, saline water in the sandstone aquifer may be invading fresh water in the St. Peter Sandstone because of pumping, and entering the Niagara Dolomite through wells having deteriorated casings (Skinner and Borman, 1970). Improper construction of wells and the deterioration of casing and seals are common causes for contamination of both shallow and deep ground-water supplies. A well-construction and pump-installation code of the Wisconsin Department of Natural Resources (1953) is designed to protect ground-water supplies from surface and near-surface contaminants. This code specifies depth and type of casing, cementation, plugging, and other methods for safeguarding the quality of ground water. Proper construction of wells and a knowledge of ground-water occurrence and movement contribute greatly to protection of ground-water quality.

MONITORING OF CHANGES IN QUALITY OF GROUND WATER

Determining the short-term, as well as the long-term, changes in ground-water quality resulting from contaminants on or below the land surface may become increasingly necessary. Contamination sources include solid- and liquid-waste disposal and storage sites, septic tanks, irrigated fields, and others. Rapidly increasing use of the land surface for disposal of liquid and solid waste (subject to leaching), increased pumping of wells, and similar activities will contaminate ground water in places where it is not acceptable.

Because movement of contaminated ground water cannot be delineated as readily as that of contaminated surface water, changes in quality and movement of pollutants are determined by monitoring through a network of sampling wells.

Objectives for monitoring ground water include the following:

1. Determine whether contaminated water is moving toward a well, spring, stream, or lake.

2. Determine the distribution, direction, and rate of movement of contaminated water from point and area sources.

3. Determine changes in the quality of "natural" ground water and in the character of the contaminant.

Most contaminants move with ground water under the influence of gravity and differences in pressure from points of high potential to points of low potential. However, some contaminants, such as gasoline or sulfite liquor, may move at different rates than ground water.

The monitoring of local changes in ground-water quality and the movement of contaminants from point and area sources requires sample collection at frequent intervals, certainly more frequent than the regional monitoring interval of 1 year.

CONCLUSIONS

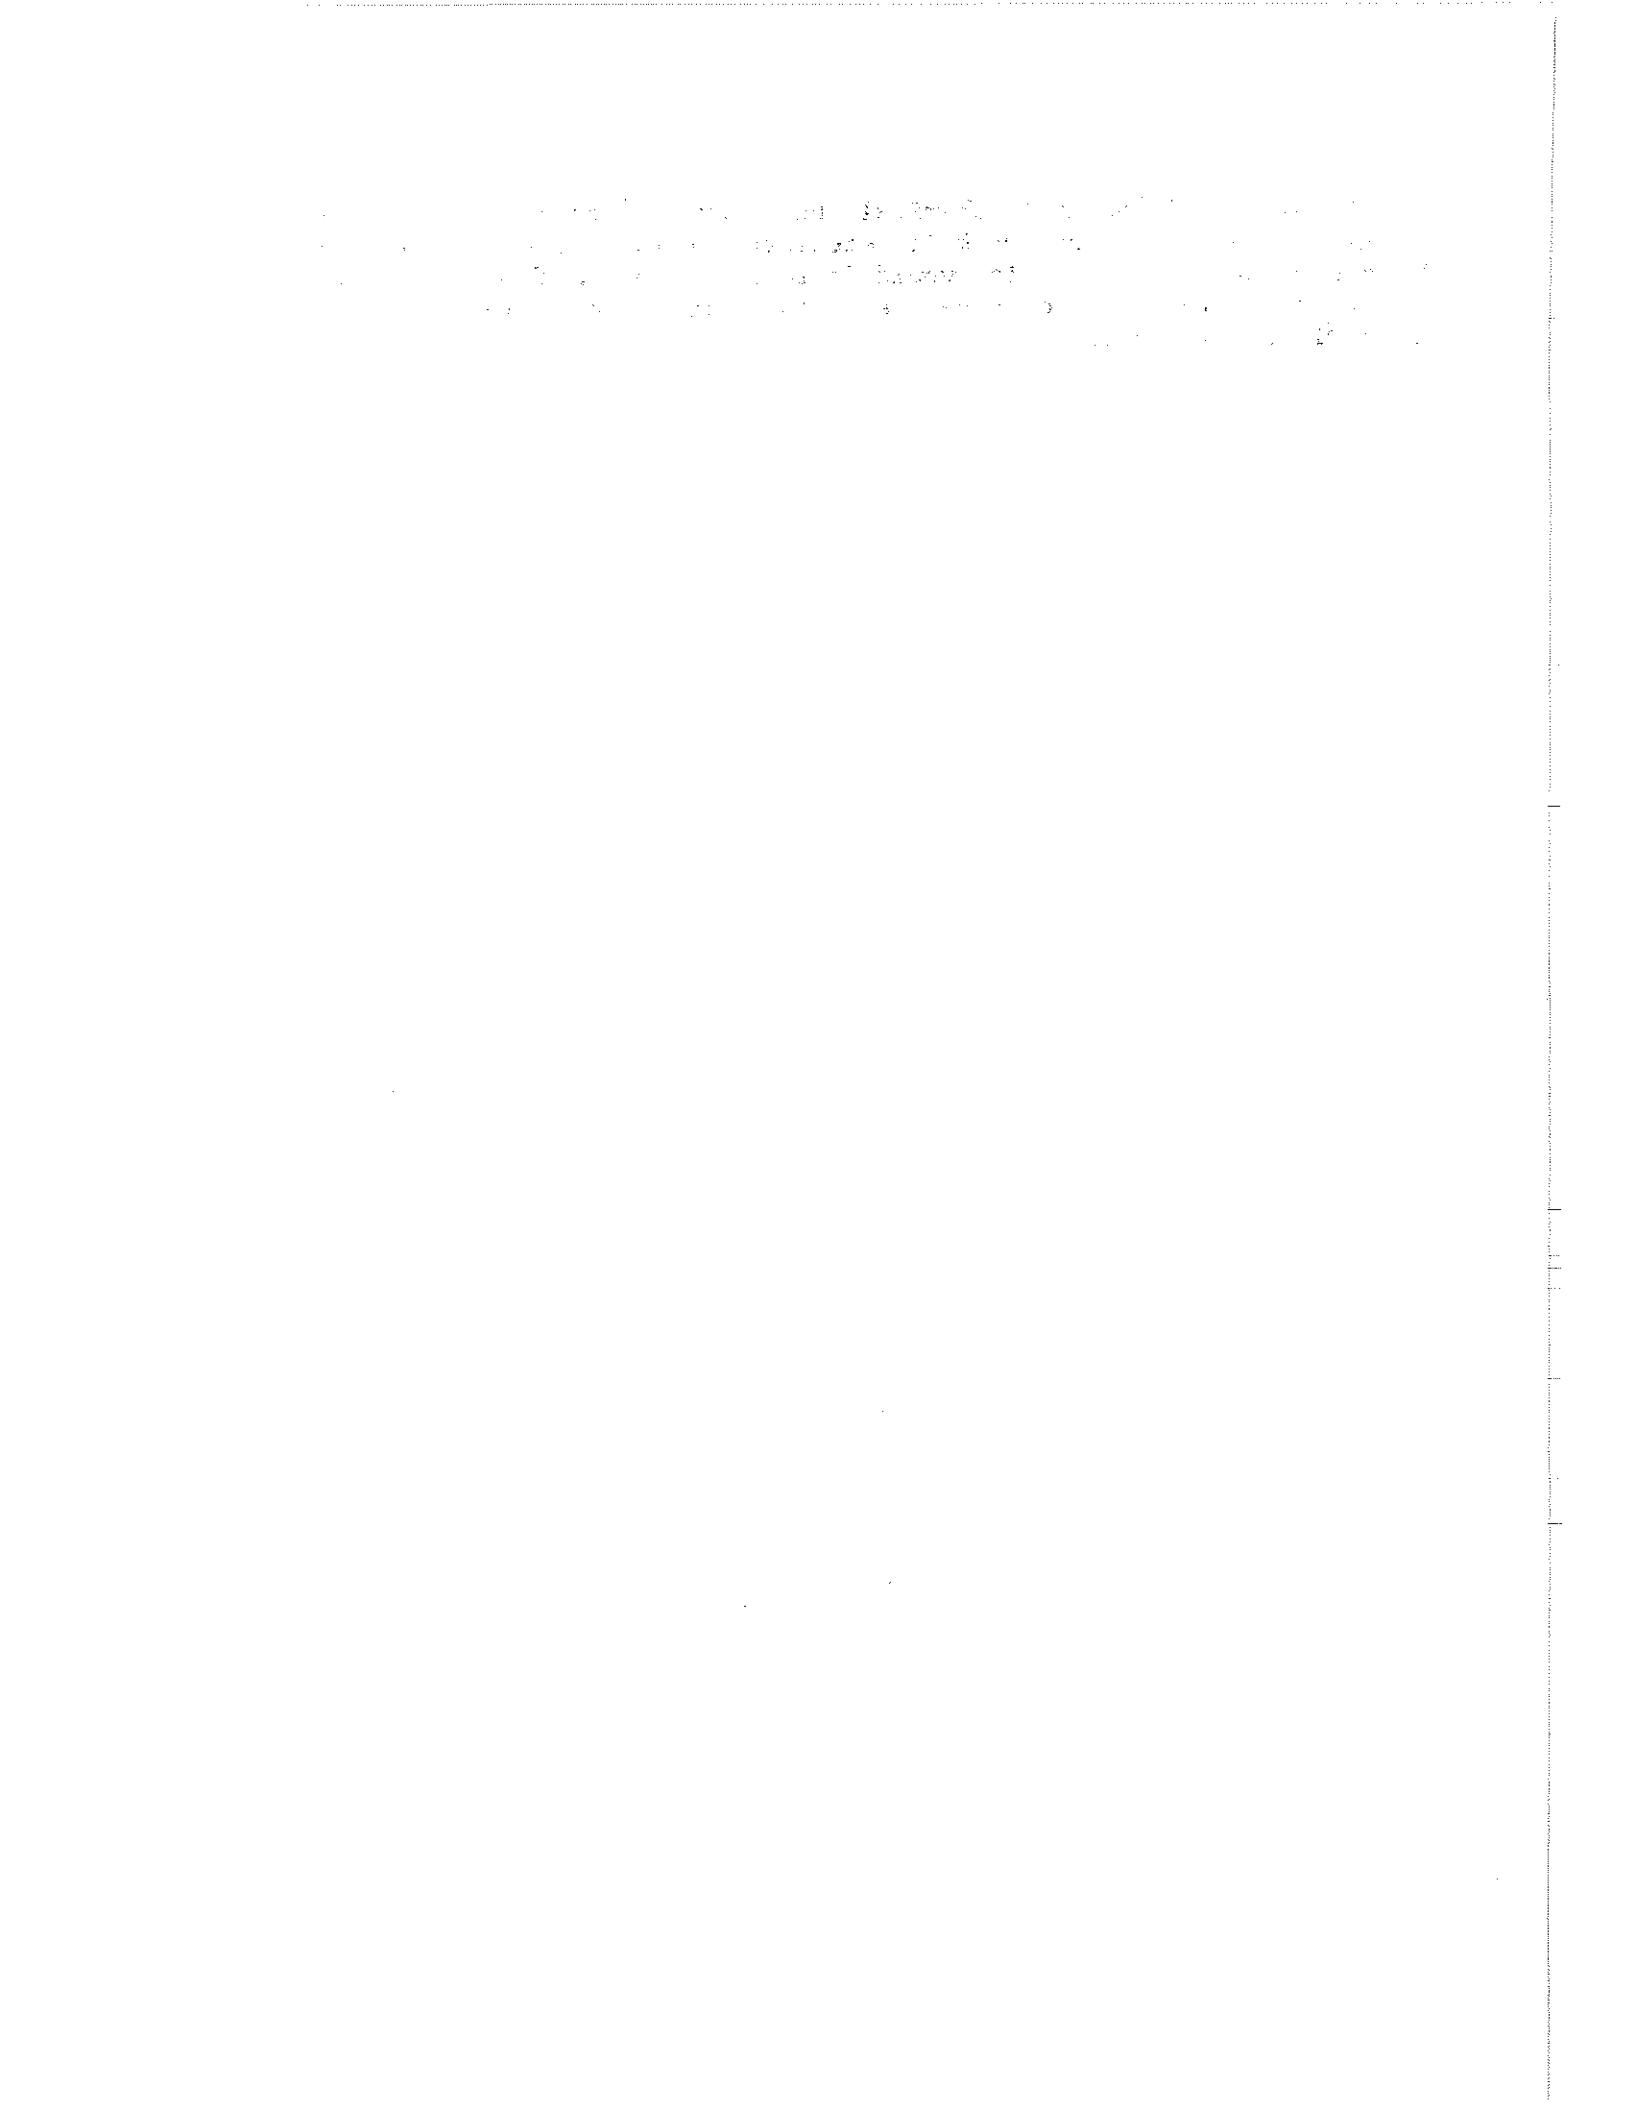

The collection of information on ground-water quality, ideally, would define the "natural" chemical character of each substantial body of fresh ground water that is used or is usable. The data so collected could constitute the base for comparison with future changes in ground-water quality. In extensive aquifers where the quality is nearly uniform and varies little with time, such as the sandstone aquifer of southern Wisconsin, present spacing of sampling points may adequately define the quality. However, less extensive aquifers, such as sand and gravel deposits in glacial drift and those of less uniform character, such as fractured dolomitic limestone, require more closely spaced networks of sampling points for adequate definition. Commonly, a one-time sample from each point in the network would define the "natural" quality of the several waters.

Multidepth arrays of sampling points could differentiate chemically dissimilar waters at different depths in the same aquifer or in multiple aquifers.

Monitoring of long-term and regional changes in quality of ground water, ideally, would include less extensive and less uniform aquifers. Collecting samples from wells tapping representative aquifers, in which hydrogeologic framework or model studies have described the behavior of water, would give optimum results with the least cost. Samples collected at intervals greater than 1 year would probably indicate changes in ground-water quality.

Contaminants from the land surface jeopardizing the "natural" quality of ground water can be monitored wherever it is essential for protection. A monitoring prerequisite would be to define the hydrogeologic framework, which directly relates to the movement of water and contaminants carried in the water. The frequency of sampling would depend on the hydrogeology and spacing of sampling wells in relation to the source of contamination. Another prerequisite would be to evaluate the "natural" quality of the ground water in relation to the characteristics of the particular contaminants. A three-dimensional array of sampling wells could be used to monitor the direction and extent of movement of contaminated water.

Knowledge of "natural" chemical character of ground water and functioning of the hydrogeologic framework is necessary for water planning and managing. Optimum planning and managing would include monitoring changes in quality of ground water, in time and space, as dictated by changes in water use and disposal of contaminants.

SHORT HISTORY OF THE ICE AGE IN WISCONSIN

The Pleistocene Epoch or "Ice Age" began about 1,000,000 years ago which, in terms of geologic time, is a very short time ago. There were four separate glacial advances in the Pleistocene each followed by an inter-glacial period when the ice receded. The fourth glacial stage is called the Wisconsin Stage because it was in this State that it was first studied in detail.

The glaciers were formed by the continuous accumulation of snow. The snow turned into ice which reached a maximum thickness of almost two miles. The ice sheet spread over Canada and part of it flowed in a general southerly direction toward Wisconsin and neighboring states.

The front of the advancing ice sheet had many tongues or "lobes" whose direction and rate of movement were controlled by the topography of the land surface over which they flowed and by the rates of ice accumulation in the different areas from which they were fed.

The ice sheet transported a great amount of rock debris called "drift". Some of this was deposited under the ice to form "ground moraine" and some was piled up at the margins of the ice lobes to form "end moraines". "Drumlins" are elongated mounds of drift which were molded by the ice passing over them and hence indicate the direction of ice movement.

The pattern of end moraines, in red, shows the position that was occupied by four major ice lobes. One lobe advanced down the basin of Lake Michigan, another down Green Bay, a third down Lake Superior and over the northern peninsula of Michigan and yet a fourth entered the state from the northwest corner. The well-known "Kettle Moraine" was formed between the Lake Michigan and Green Bay lobes. As the ice melted the drift was reworked by the running water. Large amounts of sand and gravel were deposited to form "outwash plains"; pits were formed in the outwash where buried blocks of ice melted and many of these are now occupied by lakes.

The action of the ice profoundly modified the landscape, smoothing off the crests of hills and filling the valleys with drift. In some places it changed the course of rivers forcing them to cut new channels such as that of the Wisconsin River at the Dells; elsewhere it dammed the valleys to create lakes such as those of the Madison area.

During recent years there have been intensive studies made of the polar ice caps, and methods have been developed for dating glacial events from the radioactivity of the carbon in wood, bones, etc. which are found in many of the deposits. The results of these studies are causing many previously accepted concepts to be changed or challenged.

We once thought that there were rather extensive glacial deposits older than Wisconsin age in the State, but age determinations do not support this. It was also thought that the ice left Wisconsin some 20,000 years ago but a forest at Two Creeks in Manitowoc County was buried under an advancing ice tongue only 11,000 years ago. Evidence is accumulating to indicate that ice may have occupied the so-called "Driftless Area" of the southwestern part of the State which hitherto has been held to be unglaciated.

Most scientists now believe that the cause of the Pleistocene "Ice Age" was due to variations in the solar energy reaching the earth, but how these may have occurred is still a matter of conjecture. We are still in the Ice Age and it is anybody's guess whether future millenia will see the melting of the ice caps and the slow drowning of our coastal cities, or the regrowth and once more the inexorable advance of the glaciers.

SHORT GEOLOGIC HISTORY OF WISCONSIN

The bedrock of Wisconsin is separated into two major divisions: (1) older, predominantly crystalline rocks of the Precambrian Era; and (2) younger relatively flat-lying sedimentary rocks of the Paleozoic Era.

The Precambrian Era lasted from the time the earth cooled, over 4,000 million years ago, until the Paleozoic Era which began about 600 million years ago. During this vast period of 3,400 million years sediments, some of which were rich in iron and which now form iron ores, were deposited in ancient oceans; volcanoes spewed forth ash and lava; mountains were built and destroyed, and the rocks of the upper crust were intruded by molten rocks of deep-seated origin. Only a fragmentary record of these events remains but, as tree stumps attest to the presence of former forests, the rocky roots tell the geologist of the presence of former mountains. Nowhere does any trace of the original crust remain, and the oldest rocks yet found in the state are about 2,000 million years old. With the exception of the Upper Keweenawan formations that outcrop in the northwest, all of these rocks have been extensively deformed, and in many areas they are so highly altered that their original nature and origin are extremely difficult to interpret.

In the north-central part of the state surface outcrops are so sparse, due to a cover of glacial deposits, that details of the bedrock are obscured. In such areas the only clues to the underlying rocks are obtained indirectly by such geo-physical methods as airborne magnetics. In the past much high-grade iron ore was produced from the Precambrian rocks of northern Wisconsin, and much low-grade ore ("taconite") awaits development. Recent geologic work indicates that the area has a high potential for finding ores of other metals such as copper.

At the close of the Precambrian Era most of Wisconsin had been eroded to a rather flat plain upon which stood hills of more resistant rocks as those now exposed in the Baraboo bluffs. There were still outpourings of basaltic lava in the north and a trough formed in the vicinity of Lake Superior in which great thicknesses of sandstone were deposited.

The Paleozoic Era began with the Cambrian Period, the rocks of which indicate that Wisconsin was twice submerged beneath the sea. Rivers draining the land carried sediments which were deposited in the sea to form sandstone and shale. Animals and plants living in the sea deposited calcium carbonate and built reefs to form rocks which are now dolomite—a magnesium-rich limestone. These same processes continued into the Ordovician Period during which, as indicated by the rocks, Wisconsin was submerged three more times. Deposits built up in the sea when the land was submerged were partially or completely eroded at times when they were subsequently elevated above sea level. During the close of the Ordovician Period, and in the succeeding Silurian and Devonian Periods, Wisconsin is believed to have remained submerged.

The youngest rocks outcropping in Wisconsin are of Devonian age and are about 350 million years old. Absence of younger rocks makes interpretations of post-Devonian history in Wisconsin a matter of conjecture. If the dinosaurs roamed Wisconsin, as well they might have some 200 million years ago, no trace of their presence remains. Available evidence from neighboring areas, where younger rocks are present, indicates that towards the close of the Paleozoic Era, perhaps some 250 million years ago, a period of gentle uplift began which has continued to the present. During this time the land surface was carved by rain, wind and running water.

The final scene took place during the last million years when glaciers invaded Wisconsin from the north and sculptured the land surface. They smoothed the hill tops, filled the valleys and left a deposit of debris over all except the southwest quarter of the State where we may now still see the land as it might have looked a million years ago.

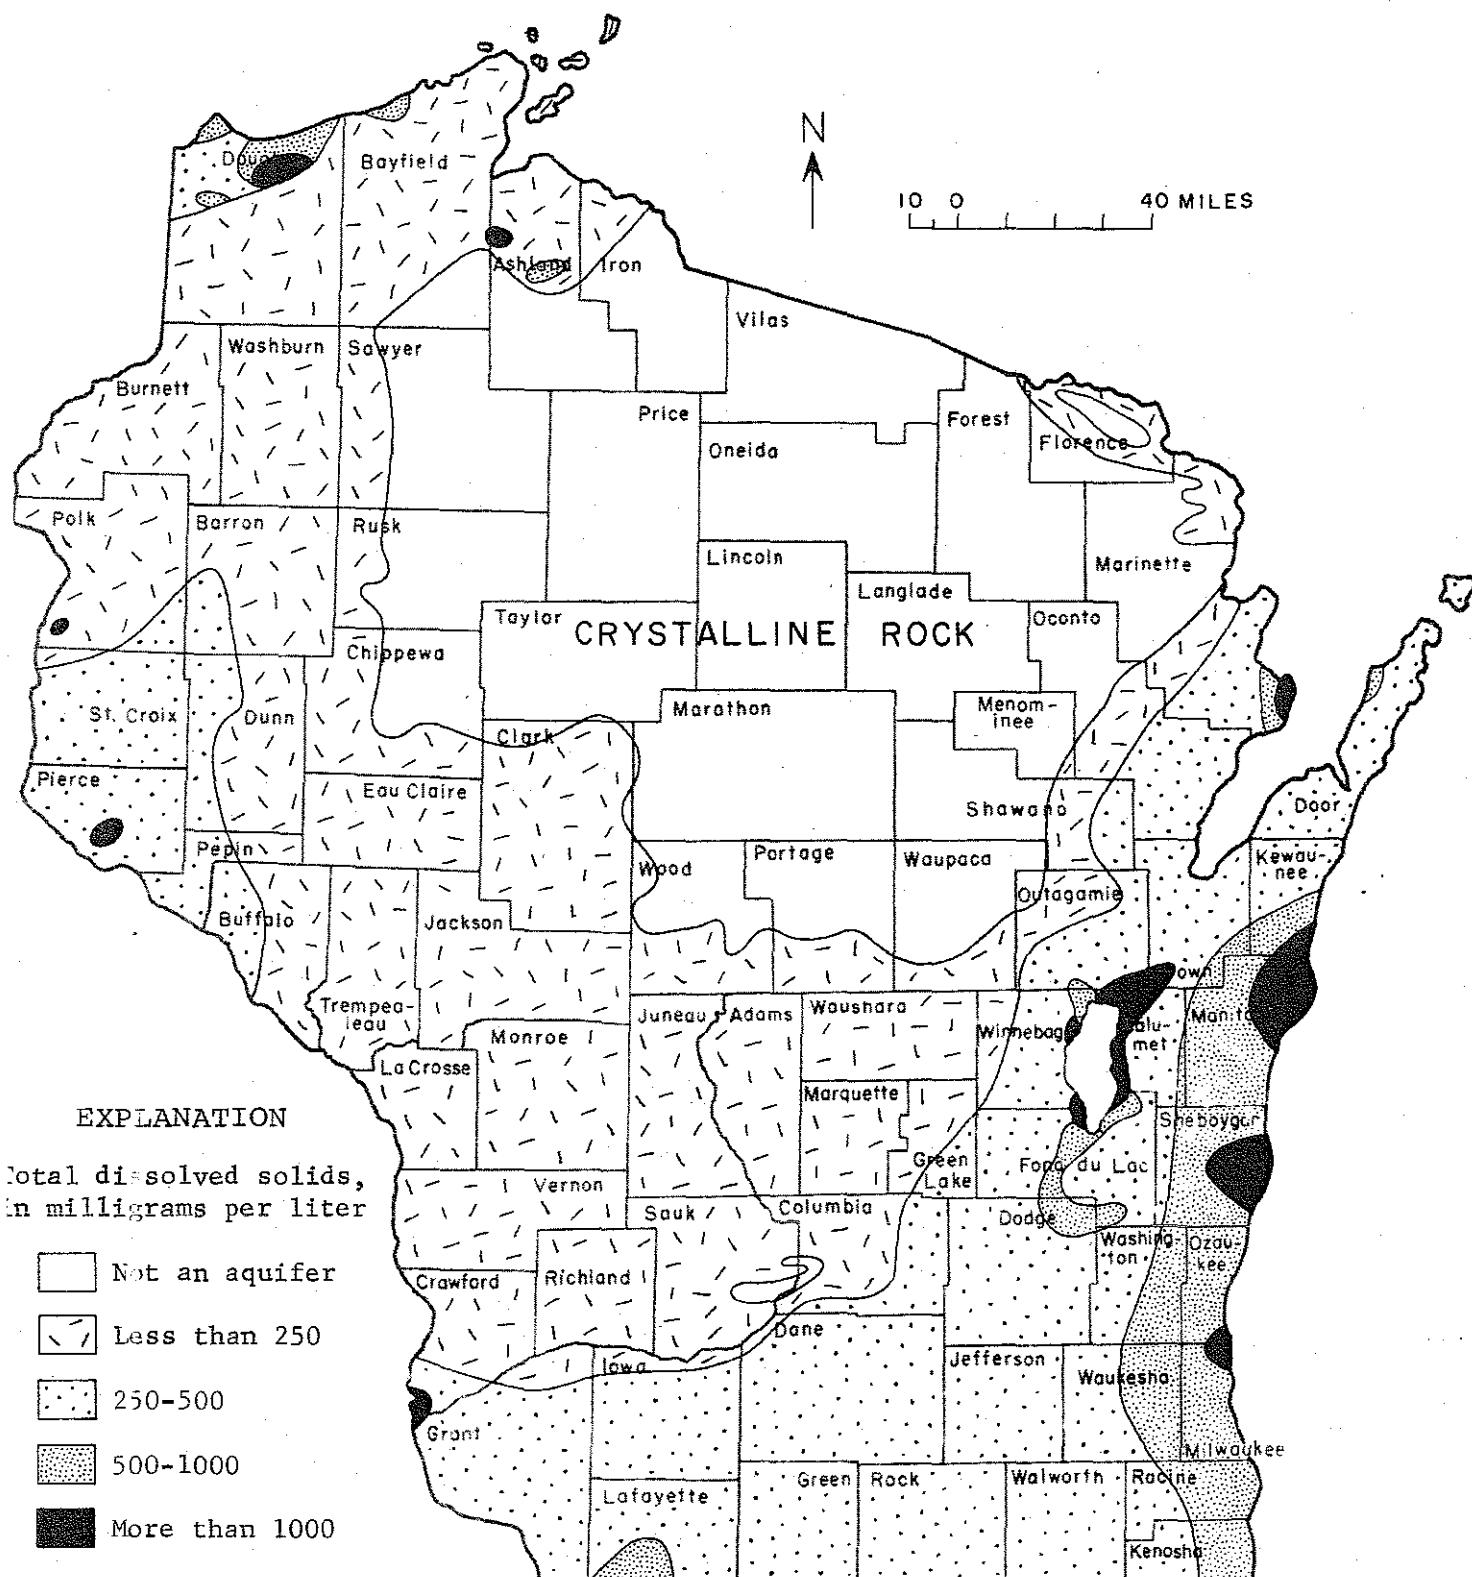

Figure 5. Quality of water in deep bedrock.

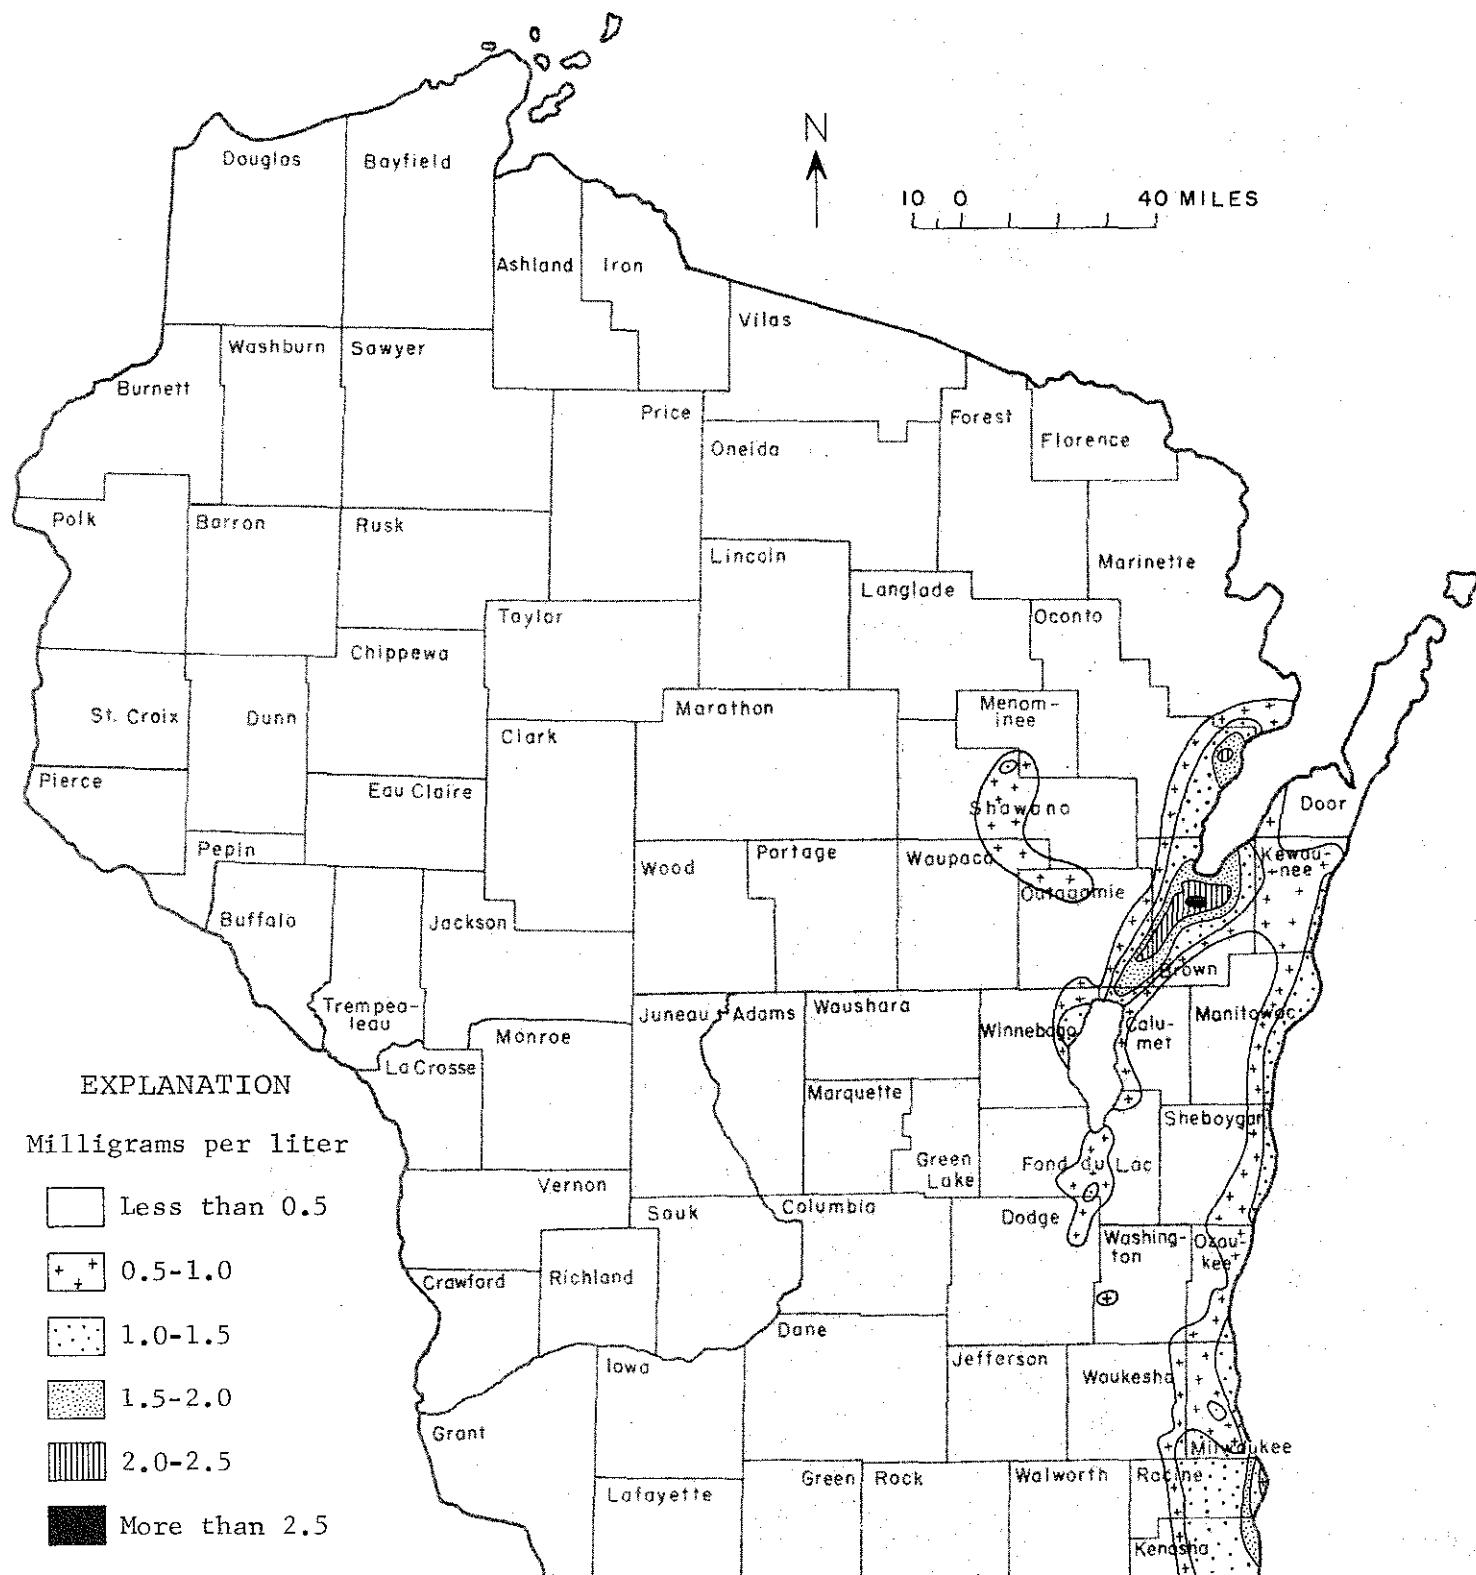

Figure 6. Fluoride in ground water.

EXPLANATION FOR TABLE 1

The table that follows is a statewide compilation of analyses of chemical constituents and physical properties of water from many aquifers. It includes analyses by the U.S. Geological Survey, the Wisconsin Department of Natural Resources, the Wisconsin Laboratory of Hygiene, and other government and private laboratories. The table represents data collected and coded in an automatic-retrieval format, principally as a result of the cooperative program between the U.S. Geological Survey and the Wisconsin Geological and Natural History Survey. Some of the work has been done in cooperation with the Wisconsin Department of Natural Resources. Work is continuing in the coding of historical data and the collection of new data on ground-water quality.

Table 1 is a printout of selected parameters from well records and the chemical analyses. Much more information is stored for the wells, and additional chemical-quality data are recorded for nearly all analyses. The selected parameters are summarized, as follows, in table 1.

40/18/28-0007			
WELL LOCATION AND CO NUMBER	Township	Range	Section
OWNER	Name of well owner (abbreviated where necessary)		
WELL DPTH	Depth of the well, in feet		
AQUIFER	Principal water-bearing reservoir yielding water to the well		
GLACIAL - unconsolidated glacial deposits			
NIAGARA - dolomite of Silurian age			
DOL-SS - any or all of the dolomite in the Galena-Platteville unit, the St. Peter Sandstone, and the dolomite of the Prairie du Chien Group			
SANDSTONE - principally Cambrian sandstone but may include formations within DOL-SS			
PRECAMB - rocks of Precambrian age: dense crystalline rock; also includes lava flows and the Lake Superior sandstone (of former usage) in northwestern Wisconsin			
MULTIPLE - a combination of two or more of the above aquifers			
DATE ANALYS	The date on which the water sample was collected: 062266 is June 22, 1966		

FE +MN	The sum of iron and manganese concentrations, in milligrams per liter
CA	Calcium concentration, in milligrams per liter
MG	Magnesium " "
NA	Sodium " "
K	Potassium " "
HCO ₃	Bicarbonate " "
CO ₃	Carbonate " "
SO ₄	Sulfate " "
CL	Chloride " "
F	Fluoride " "
NO ₃	Nitrate " "
DIS SOLIDS	Dissolved-solids content, in milligrams per liter
HARD- NESS	Hardness, in milligrams per liter as CaCO ₃
