

Preliminary water-table elevation map of Columbia County, Wisconsin

Wisconsin Geological and Natural History Survey
Open-File Report 2012-04

Stephen M. Sellwood

What is a water-table map?

This map shows the approximate elevation of the water table in Columbia County. The water table represents the top of the saturated zone. Below the water table, all pores, cracks, fissures, and other voids in the subsurface are filled with water. Above the water table these voids are mostly filled with air. The water table is the elevation below which water will freely fill a hole or well. Streams, lakes, and wetlands in the county are places where the water table intersects the land surface.

The water table level fluctuates seasonally in response to periods of precipitation, snowmelt, and drought. These fluctuations are greatest where the water table is highest in the landscape and far from surface water features.

What the map shows

The contour lines on the map represent lines of uniform elevation of the water table, in feet above mean sea level. For instance, at every point along the 800-foot contour, the water table is present at 800 feet above sea level.

Water-table elevations are lowest (about 740 to 780 feet above sea level) along the Wisconsin River and Lake Wisconsin in the southwest part of the county, and are highest (over 1400 feet above sea level) in the Baraboo Hills region of the county.

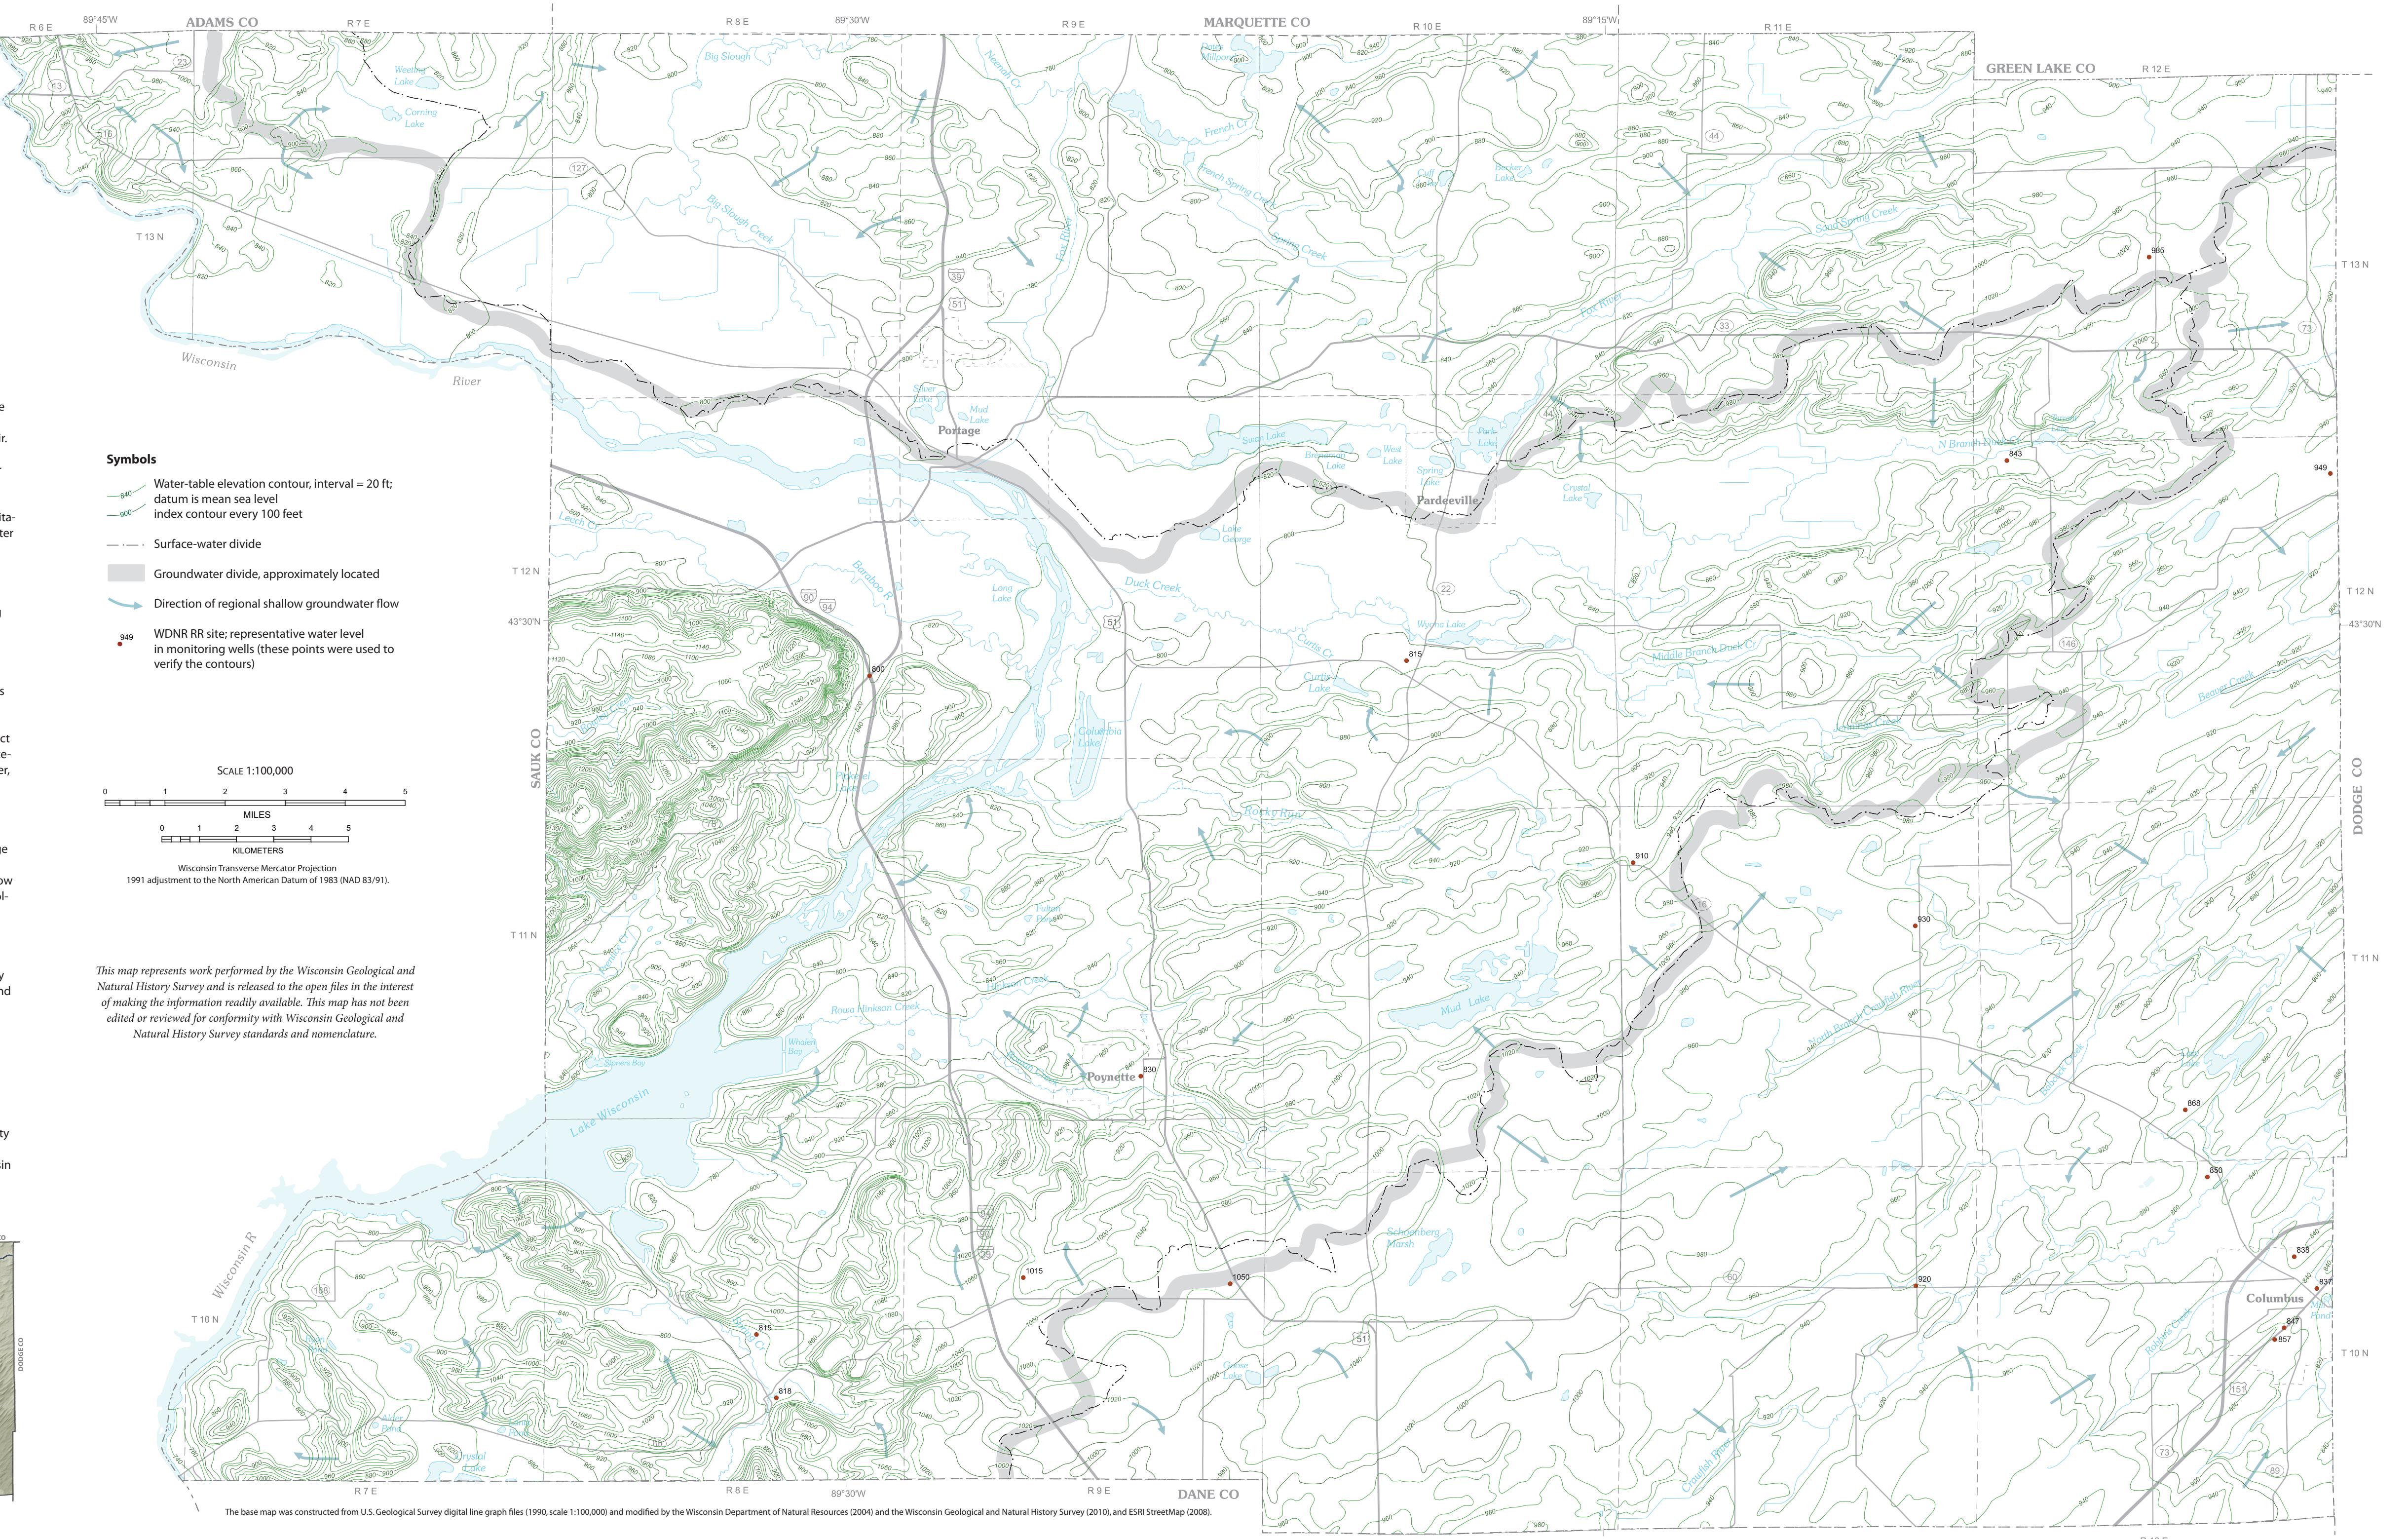

A surface-water divide is a ridge along the highest elevations of the water table. Groundwater flows away from divides, toward groundwater discharge areas such as lakes and rivers. Groundwater typically moves in directions approximately perpendicular to the water-table contours. (Groundwater flow in the Baraboo Hills is an exception and is discussed in more detail in the following section.)

The major groundwater divides in Columbia County are along or relatively close to surface-water divides. Groundwater divides are illustrated on this map as wide and approximate areas because the location of the divide may change as the water table rises and falls in response to periods of rainfall and drought. Significant amounts of groundwater pumping from wells drilled near divides may also cause a divide to shift. In contrast, surface-water divides are fixed by ground surface topography and do not move.

The groundwater divides in Columbia County can be used to separate the areas in which groundwater flows toward particular stream systems. For example, in the south and east region of Columbia County, groundwater flows toward and discharges to the tributaries, lakes, and wetlands within the Rock River basin, or to the Rock River itself. In northern Columbia County groundwater discharges within the Fox River basin, and for a large part of west and central Columbia County, groundwater discharges in the Wisconsin River basin.

Figure 1. Shaded relief map showing drainage basins as well as topographic and geologic features that influence the water table in Columbia County.

The base map was constructed from U.S. Geological Survey digital line graph files (1990, scale 1:100,000) and modified by the Wisconsin Department of Natural Resources (2004) and the Wisconsin Geological and Natural History Survey (2010), and ESRI StreetMap (2008).

Construction of the map

Groundwater elevations were estimated from the elevations of surface-water features such as streams, lakes, and wetlands. Water-table elevation contours for this map are interpolated from the elevations of surface water features and inferred from ground surface topography.

Mapped water-table elevations were verified at several locations throughout the county using water-table elevation data obtained from the Wisconsin Department of Natural Resources online database of closed remediation sites. These data consist of water level elevations measured in monitoring wells installed at contamination investigation sites. Monitoring wells are excellent indicators of water-table elevation because they are often screened across or just below the water table, and water levels are often repeatedly measured. The locations and approximate water-table elevations of these data are indicated as red points on the map.

The accuracy of the map varies throughout the study area, increasing where surface-water bodies are more prevalent. Water-table elevation contours are less accurate in areas of steeper topographic relief, such as in the Baraboo Hills and south of Lake Wisconsin (fig. 1). The water-table elevations are also subject to seasonal fluctuations in recharge or as a result of large-volume pumping from wells. However, the groundwater flow directions are not typically affected by seasonal variations in recharge.

The water table is heavily influenced by surface topography. The general surface topography of Columbia County is shown in the shaded-relief map (fig. 1). The following paragraphs discuss some of the topographic and geologic features in the county and their influence on the mapped water table.

Baraboo Hills

The Baraboo Hills form a topographic high in western Columbia County beginning west of the Wisconsin River and extending well into Sauk County to the west. The Baraboo Hills consist of Precambrian quartzite and Cambrian sandstone covered in many places by a thin layer of glacially deposited sediment. The Baraboo Hills are the highest and steepest landscape in Columbia County, and as a result, the water table within the Baraboo Hills is also higher and steeper than elsewhere in the county.

The quartzite bedrock of the Baraboo Hills is relatively impermeable; groundwater flows primarily through fractures in the rock. Although the water table is mapped as a continuous surface across this area, groundwater flow directions in fractured rock aquifers can be more complex than in porous aquifers. Flow directions in the quartzite may not be predicted accurately from the mapped water-elevation contours; flow-direction arrows are not shown for this area. In addition, wells installed into the quartzite bedrock may not produce significant amounts of water, and these wells will likely not produce water levels consistent with the mapped water table unless they intersect near-surface fractures.

Sandstone ridges

The water table in the southwest corner of Columbia County contains notable areas of raised relief where the water-table elevation rises above nearby surface water features. These areas coincide with bedrock ridges that consist predominantly of sandstone. In these areas the mapped water table is also mapped as a raised feature, but it is more subdued than the surface topography.

Drumlins

Along the eastern boundary of Columbia County, the water table takes on a linearity trending generally northeast-southwest. This linearity is due to the presence of drumlins on the land surface in this part of the county. The drumlins influence the shapes of surface water features and the shape of the water table.

Uses of the map

This water-table elevation map has a wide variety of uses. The map can be used to identify where a spill will move or to trace a contaminant back to its source by looking at the approximate direction of groundwater flow. Knowing the direction of groundwater flow can also be used to help protect both the quantity and quality of water that feeds lakes and streams. Another use for the map is to calculate depth to the water table, a key component in estimating groundwater susceptibility. Depth to water table data is important for construction activities such as excavations, foundation design, and highway planning.

Map credits

Data used to generate this water-table map were compiled by Steve Mauel, Andrew Aslesen, and Kathy Roushar of the Wisconsin Geological and Natural History Survey. U.S. Geological Survey digital data for hydrography (derived from USGS, 2001), topographic quadrangles (7.5-minute series; USGS, 1996-97), and the National Elevation Dataset (USGS, 2001) were used as aids in estimating groundwater elevations and contouring the data.
